**ABSTRACT**

**Context** N-methyl carbamate insecticides are widely used in homes, gardens and agriculture. They share the capacity to inhibit cholinesterase enzymes with organophosphates and therefore share similar symptomatology during acute and chronic exposures. One of the serious effects of organophosphate and carbamate intoxication is the development of acute pancreatitis and subsequent intrapancreatic fluid formation.

**Case report** An 18-year old Caucasian man was admitted to our Intensive Care Unit with cholinergic crisis symptomatology, after the ingestion of an unknown amount of a carbamate insecticide (methomyl). Pseudocholinesterase levels were 2 kU/L on the day of admission (reference range: 5.4-13.2 kU/L). Two days after admission, an abdominal CT scan revealed blurring of the peripancreatic fat planes, inflammation and swelling of the pancreas, and a substantial amount of ascitic fluid in the left anterior pararenal space and pelvis. Paracentesis and analysis of the ascitic fluid demonstrated findings diagnostic of pancreatic ascites. There had been no other evident predisposing factors for acute pancreatitis, other than methomyl intoxication. Eleven days after admission, pseudocholinesterase levels returned to normal, while a new abdominal CT scan revealed the formation of intrapancreatic fluid collection. The patient was discharged in good physical condition two weeks after admission. A follow up abdominal CT scan performed one month later showed a significant reduction in the size of the intrapancreatic fluid.

**Discussion** Acute pancreatitis is not uncommon after organophosphate intoxication and carbamates share the same risk as organophosphorus pesticides. The development of acute pancreatitis and subsequent intrapancreatic fluid collection after methomyl intoxication has not previously been reported. This is the first case reported of acute pancreatitis and pancreatic ascite formation after anticholinesterase insecticide ingestion.

**INTRODUCTION**

Carbamate insecticides are widely used in agriculture and home gardening [1, 2, 3]. They are derivatives of carbamic acid (as the organophosphates are derivatives of phosphoric acid) and, like organophosphates (OPs), their mechanism of action is that of inhibiting the vital enzyme cholinesterase (ChE) [1, 2, 3, 4]. ChE inhibition by carbamates is reversible but ChE inhibition by organophosphates is irreversible. This is why carbamate poisonings tend to be of shorter duration, unlike the permanent cholinesterase
binding induced by organophosphates [4]. When ChE is inhibited by a carbamate, it is said to be “carbamylated”, as an OP causes an enzyme to be “phosphorylated”. In insects, the effects of OPs and carbamates are primarily those of poisoning of the central nervous system, since the insect neuromuscular junction is not cholinergic, as in mammals. The only cholinergic synapses known in insects are in the central nervous system.

N-methyl carbamate esters, by causing reversible carbamylation of the acetylcholinesterase enzyme, allow accumulation of acetylcholine (increase of acetylcholine activity) - the neuromediator substance - at parasympathetic neuroeffector junctions (muscarinic effects), at skeletal muscle myoneural junctions and autonomic ganglia (nicotinic effects), and in the brain (central nervous system effects) [1, 2, 3, 4]. At the cholinergic nerve junctions with smooth muscle and gland cells, high acetylcholine concentration causes muscle contraction and secretion, respectively. At the skeletal muscle junctions, excess acetylcholine may be excitatory (causing muscle twitching), but may also weaken or paralyze the cell by depolarizing the end-plate. In the brain, elevated acetylcholine concentrations may cause sensory and behavioral disturbances, incoordination, and depressed motor function (rarely seizures), even though the N-methyl carbamates do not penetrate the central nervous system very efficiently. Respiratory depression combined with pulmonary edema is the usual cause of death from poisoning by N-methyl carbamate compounds. A serious side effect of organophosphate and carbamate intoxication is the development of acute pancreatitis1 [1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12].

We describe the case of a patient who developed acute pancreatitis, pancreatic ascites and subsequent intrapancreatic fluid collection after the ingestion of methomyl, a carbamate insecticide. The development of acute pancreatitis and subsequent intrapancreatic fluid collection after methomyl intoxication has not previously been reported and this is the first case reported of acute pancreatitis and pancreatic ascite formation after anticholinesterase insecticide ingestion.

CASE REPORT

An 18-year-old Caucasian man was admitted to our Intensive Care Unit with cholinergic crisis symptomatology, after the deliberate ingestion of an unknown amount of a carbamate insecticide (methomyl), in an unsuccessful suicide attempt. His family presented us with an empty bottle of a methomyl insecticide (Lannate), found in the kitchen. The patient was not on any medication, had no history of alcohol abuse and had an unremarkable medical record. On admission, the patient presented in comatose condition (Glasgow Coma Scale 3/15). His heart rate was 110 beats per minute and his blood pressure was 210/145 mmHg; he had labored breathing and tachypnea, excess sweating and his temperature was 37.5°C. Clinical examination revealed pinpoint pupils whereas auscultation of all the lung fields revealed rales as well as generalized ronchi. He had profuse salivation and peristalsis of the gastrointestinal tract was markedly increased. There were no electrocardiographic abnormalities. Chest radiograph showed diffuse bilateral infiltrates. Heart size was normal. On blood gas analysis, the pH was 7.32 with HCO3 17 mmol/L, partial arterial pressure of oxygen (Pa(O2)) was 56 mmHg and partial arterial pressure of carbon dioxide (Pa(CO2)) was 76 mmHg. A complete blood count showed an elevation of the white blood cell count with neutrophil predominance. Glucose, ALP, creatine kinase and its isoform creatine kinase isoform MB were all increased while pseudocholinesterase levels were markedly decreased. The rest of the biochemical parameters measured on admission were within normal limits (Table 1). Urine microscopy was normal.

The patient was immediately transferred to the Intensive Care Unit where endotracheal intubation was performed since mechanical
ventilation was considered necessary. An orogastric tube was inserted and continuous gastric lavage as well as suction of bronchial secretions were continuously carried out, while all his clothes were taken off and the patient’s skin was decontaminated using large amounts of water and soap. Two mg of atropine were given every 15 minutes intravenously in order to achieve atropinization (clearing of bronchial secretions, dry mouth). Pupil size was not considered an end-point of atropine administration.

A total of 60 mg of atropine was needed over the next 6 days in order to achieve the above goal. The patient’s level of consciousness was gradually ameliorated and artificial respiration was ended 32 hours later. Two days after admission, he complained of upper abdominal steady pain with a band-like radiation to the back. Clinical examination revealed generalized abdominal tenderness and mild distension, without signs of peritoneal irritation. Bowel sounds were markedly decreased. Serum amylase levels were 325 IU/L (Table 1). Considering the abdominal distress of the patient and the high levels of serum amylase, pancreatitis was suspected and a computed tomography scan one hour later demonstrated blurring of peripancreatic fat planes, inflammation and swelling of the pancreas, and a substantial amount of ascitic fluid in the left anterior pararenal space and pelvis (Figure 1).

The imaging findings, along with serum amylase elevation and the patient’s symptoms confirmed the diagnosis of acute pancreatitis. There had been no other predisposing factors

Figure 1. Dual phase CT showing blurring of peripancreatic fat planes, inflammation and swelling of the pancreas and a substantial amount of ascitic fluid in the left anterior pararenal space.
for acute pancreatitis were evident, other than methomyl intoxication. The Ranson criteria number on presentation was 2.

Paracentesis and analysis of the ascitic fluid performed the same day demonstrated findings diagnostic of pancreatic ascites: the combination of a serum-ascites albumin gradient below 1.1 g/dL and elevated ascitic fluid amylase (Table 1).

The patient was treated with total parenteral nutrition and imipenem.

The serial blood count over the next few days showed a decrease in all cell lines consistent with a dramatic improvement in the patient’s symptoms. Serial biochemical values over the same period showed normalization of all parameters except amylase levels which were slightly above normal. Ranson’s criteria during the first 48 hours remained two.

Pseudocholinesterase levels increased gradually, but remained below normal for 11 days.

Ten days after admission, a new abdominal CT scan revealed the formation of intrapancreatic fluid collection.

The patient was discharged in good physical condition 2 weeks after admission. A follow-up abdominal CT scan performed a month later showed a significant reduction in the size of the fluid collection.

**Discussion**

Acute pancreatitis as a complication of OP intoxication is not an uncommon condition. Its incidence in adults is 12.76% [6] and is higher in children [3]. Carbamates share the same risk of pancreatitis as OP pesticides [4]. Usually, complications - such as pancreatic necrosis - are quite rare [7, 11] and they can also occur secondary to cutaneous exposure to an organophosphate [8]. However, mortality following OP poisoning remains high despite adequate respiratory support, intensive care, and specific therapy with atropine. One-third of the patients needing mechanical ventilation and reaching Intensive Care Units die within the first 72 h of poisoning. Systolic blood pressure of less than 100 mmHg and the necessity of a FiO2 greater than 40% to maintain adequate oxygenation are predictors of a poor outcome in patients mechanically ventilated in the Intensive Care Unit [13].

In previous case reports, severe acute pancreatitis with pseudocyst formation has been described in an adult woman following accidental ingestion of an anticholinesterase insecticide [11] and in an adult man after the ingestion of a carbamate insecticide after an unsuccessful suicide attempt [12]. This case report describes the formation of intrapancreatic fluid collection after the ingestion of an anticholinesterase insecticide. Significant fluid collections develop in 30-60% of cases of acute pancreatitis [14].

Regarding carbamate intoxication, four cases of acute pancreatitis have been reported [4, 5, 9, 12], but this is the first one following methomyl ingestion.

Pancreatic ductal hypertension and stimulation of exocrine pancreatic secretion secondary to cholinergic stimulation are considered to be responsible for the development of pancreatitis [1, 2, 3, 4, 15]. Furthermore, organophosphates such as echothiophate, which inhibit the two cholinesterase isoenzymes (butyrylcholinesterase and acetylcholinesterase) in the human pancreas, increase pancreatic sensitivity to acetylcholine [1, 2].

We treated the patient with total parenteral nutrition and imipenem according to recent studies which demonstrated improved outcome associated with the use of prophylactic antibiotics in patients with severe necrotizing pancreatitis [16, 17, 18, 19]. In addition, a meta-analysis of 8 controlled trials concluded that prophylactic broad-spectrum antibiotic administration reduced mortality in patients with severe acute pancreatitis [20]. However, a subsequent multicenter, placebo-controlled trial of prophylactic antibiotics in severe acute pancreatitis, which was not included in the above meta-analysis, found that there was no benefit. [21].

We recognize the possibility that there was the pancreatic inflammation as a result of the hypoxemic effect on the pancreas [4, 12].
This is the first case reported of acute pancreatitis and pancreatic ascite formation after anticholinesterase insecticide ingestion.

CONCLUSION

A serious adverse effect of carbamate intoxication is the development of acute pancreatitis which, depending on the severity of the inflammation, can lead to the development of complications such as pancreatic ascites, intrapancreatic fluid and/or pancreatic pseudocyst formation.
